Abstract

Women in rural agrarian households are constrained in their ownership of individual assets and their access to financial resources. When farm production is organized jointly at the household level, relaxing household liquidity constraints can expand the resources available to women without directing funds to them. We test this through the randomized provision of collateral-free loans to 1,429 farming households across 80 villages in India. The loan enhanced women's financial autonomy through digital banking services, accompanied by an expansion of women's access to resources. Women in households that borrowed allocated more hours to leisure and fewer to farm work on the busiest day of the agricultural season, possibly because households acquired non-mechanized farm equipment, although their total days worked across the season did not differ between treatment and control villages. The loan did not affect women's intrahousehold bargaining power but amplified in households where spouses already coordinated at baseline. The results suggest that credit to households with joint production can improve women's outcomes, such as access to resources and financial autonomy, that are often difficult to affect through targeted resource provision.

Ward, University of Florida, Subhransu Pattnaik, University of Göttingen. This paper evaluates data from an experiment registered with the American Economic Association's registry for randomized controlled trials (Kramer and Ward, 2023; https://doi.org/10.1257/rct.11616-1.0). We are grateful to the implementing partner Dvara E-Registry for facilitating an impact evaluation of their product. This project was funded by the Center for Effective Global Action (CEGA)'s Digital Credit Observatory, a Gates Foundation-supported initiative, and undertaken in the context of the CGIAR Gender Equality and Inclusion Accelerator. We thank Andrew Foster, Chrisopher Barrett, Lucia Corno and Fernanda Leite Lopez de Leon for their valuable suggestions. The authors have no relevant or material financial interests that relate to the research described in this paper.

1 Introduction

Who in the household receives resources is a central question for models of household behavior and for the design of social assistance. Many of the largest cash transfer and microfinance programs in low- and middle-income countries designate women as recipients, on the premise that their spending priorities align with program goals. Yet these programs don't always improve their economic outcomes or agency within the household (Banerjee et al., 2015; Roy et al., 2015; Green et al., 2015; Attanasio et al., 2015; Angelucci et al., 2015; Said et al., 2019). One explanation is that directing resources to women threatens the existing distribution of power, prompting resistance from other household members. Fiala (2018); Bernhardt et al. (2019) show that loan funds were appropriated and Angelucci (2008); Bobonis et al. (2013) found that cash transfers provoked male backlash, underscoring the risks that targeted interventions pose to women. By contrast, encouraging women's involvement in asset management by re-allocating an existing household asset, strengthened their control over resources and involvement in decisions without disrupting household production (Ambler et al., 2026). An important question to ask here is whether programs that reach women without targeting them can be successful. This matters most in resource-poor settings, where marginal returns from social protection and credit are largest, but also, the pecuniary and social costs of targeting are hardest to bear.

We evaluate the impact of a widely used policy instrument, collateral-free agricultural credit, on women's outcomes in India. Agricultural production in India is organized jointly at the household level, with a division of labor across tasks: most farm managers are men, while women typically undertake labor-intensive activities such as weeding, harvesting, and livestock management (Afridi et al., 2023; Gulati et al., 2025). Targeting an agricultural loan to women may therefore not change how households use the funds. The program increased asset accumulation but did not change input use or farm income in our sample, so we examine two channels through which it may affect household members, particularly women. In the consumption channel, household spending on composite goods, such as productive assets and consumer durables that members consume both jointly and individually, raises their utility, assuming they value such goods. In the residual income channel, the loan can change the contribution each member makes to household expenditure, and therefore their residual income, with corresponding effects on their financial autonomy and leisure.

In this paper, we utilize data from a cluster randomized controlled trial with 1,429 farming households in 80 villages of India. Households were offered a collateral-free *loan product* between 2023 and 2024 in 40 of the study villages (treatment group) as part of the

experiment, while the remaining 40 villages (control group) did not receive this product but could access formal and informal credit suppliers in the market. The randomization allows us to measure the causal effect of the loan product on household consumption and individual-level outcomes. The loan amount was roughly less than half of the annual household income and 99% of the beneficiaries repaid it. The loan was disbursed at the start of the planting season, when households' credit needs peak, charged about 24% interest rate, on average 10 percentage points below other credit available in the market. The lending institution earned an average profit of USD 18 per farmer.

We employ two empirical models in our analysis. First, we estimate the intent-to-treat (ITT) effect of the loan program on household spending using an analysis of covariance (ANCOVA) model. Here we exploit the cluster randomization of the loan program at the village level and a household panel dataset combining baseline and endline surveys. Second, we examine how the loan affected the outcomes of household members, focusing on their financial autonomy, time use, and involvement in decisions. The endline survey interviewed two members per household compared to one at baseline, the same farmer that was interviewed in the baseline survey and one additional household member, yielding a sample of 1,126 women. We use an Instrumental Variables (IV) model in which randomized village-level treatment assignment instruments for households that took up the loan product, henceforth known as "borrower households". Restricting the endline sample to female respondents and controlling for their position in the household, we estimate the Local Average Treatment Effect (LATE) of the program on women's outcomes. We separately estimate the impact on men and report it alongside women's results.

The program increased household accumulation of productive capital and consumer durables. The treatment group was 14 percentage points (pp) more likely to own non-mechanized farm equipment and 8 pp more likely to own large consumer durables than the control group. dietary diversity also improved as the treatment group's food consumption score was 17% greater than the control group's (39.4 vs. 33.8). Building on the households' spending response to credit, we use individual-level data and a model of intrahousehold allocation under joint production to trace how the loan product affected household members, specifically women.

The program resulted in two key impacts on women. First, it positively impacted their financial autonomy. Members in borrower households transacted from their bank account more regularly, and women were 40 pp more likely to receive deposits other than earnings or government transfers, suggesting changes in their residual income. Accompanied by expanded resource access, women exercised more financial autonomy. They were

70 pp more likely in borrower households to use the debit cards linked with their individual bank account by themselves than the control group. They were about 81 pp more likely to use mobile apps for banking. Both independent use of debit cards and mobile banking indicate financial autonomy through greater privacy of transactions. Men also experienced gains in financial autonomy. The effects for men are positive but smaller than those for women, since men's control group means are higher.

Second, women responded to the loan product by allocating more time to leisure activities (2.6 versus 1.7 hours in the control group) on the busiest day of the agricultural season. They reported fewer hours than the control group in farm work during this peak time, however, their contribution in the number of days over the entire season was not significantly different. Real wages paid for hiring farm labor for that agricultural season and annual real income from farming did not change suggesting that households' ownership of non-mechanized farm equipment may have increased women's productivity. Women reduced their labor supply to business or wage employment. Our data does not let us distinguish the mechanisms behind this reduction. There are two possible explanations. One, it could be the response of households no longer requiring additional income to supplement their budget because of the loan. Two, the decline was concentrated among households in the state of Maharashtra, and systematic social norms around women's non-agricultural labor supply could also possibly explain this pattern. In households with higher ex-ante coordination among spouses, the loan's effect on women's supply to non-farm work was significantly larger than the rest, suggesting that the loan supported women's non-farm activities in cooperative households. We find consistent patterns in women's recall of time allocations in the day prior to the survey. Men's time allocation to production or leisure did not differ between the loan product-receiving households and the control group.

The loan did not shift the balance of power between spouses as measured by women's or men's involvement in household production and consumption decisions. However, it reinforced existing cooperative household arrangements. Greater spousal coordination among households prior to the intervention corresponded positively with women's involvement in decisions on non-agricultural production activities, domestic work, household purchases, their private consumption and personal activities.

This paper contributes to the literature on women's financial inclusion and autonomous control over resources, highlighting that reducing households' liquidity constraints is an important channel to improve these outcomes. This paper finds a large impact on women's knowledge and use of mobile banking, which is striking given the otherwise low uptake of

digital finance in rural India because of rigid gender norms (Barboni et al., 2018). Our results stand in contrast to those of a targeted smartphone distribution to rural women in India, in which 40 percent of women transferred the device to another household member and the program had no aggregate effect on their knowledge or use of mobile banking (Barboni et al., 2024). Together, these findings highlight the value of program designs that improve women's financial outcomes without explicit targeting.

This paper contributes to the literature evaluating credit programs and their effects on women. Directing resources to women does not reliably improve their economic outcomes, as assets and loan funds are often appropriated by other household members. Loans to women in multi-adult households raised household income and other members' enterprise profits, but not women's own profits (de Mel et al., 2008; Garikipati, 2008; Fiala, 2018; Friedson-Ridenour and Pierotti, 2019; Bernhardt et al., 2019), and 40 percent of rural women who received smartphones through a targeted program in India transferred them to another household member (Barboni et al., 2024).

Programs that pair resources with group structures or complementary services, such as training on the use of funds, banking services, or direct messaging, have produced more positive results for women's empowerment. Savings-led programs improved women's empowerment indices in rural Ghana, Malawi and Uganda (Karlan et al., 2017) and in the Philippines (Ashraf et al., 2010), and group-based agricultural development projects improved women's instrumental and collective agency (Quisumbing et al., 2024). Even so, the effects on women's agency vary. Group-based microcredit did not improve women's involvement in decisions over household spending, investment, savings, or children's health and education in India (Banerjee et al., 2015), nor a female empowerment index capturing women's consumption and production decisions and mobility in Morocco (Crépon et al., 2015), but it increased women's involvement in decisions in Mexico (Angelucci et al., 2015). Depositing women's wages into their own bank accounts, bundled with information sessions, raised women's labor supply in India but did not affect women's involvement in decisions over the use of their money (Field et al., 2021).

Our intervention differs from these programs: it did not involve group-based saving or lending, included no bundled training that could influence women's subjective well-being or empowerment, and did not target borrowers by gender. We show that such a design can also improve women's access to resources without explicitly targeting funds to them. While we find no aggregate effects on women's involvement in decision-making, women in households with greater ex-ante bargaining power were more likely to be involved in decisions.

This paper also adds to the literature on how social protection and credit programs

affect women's labor supply. In our setting, the loan increased women's time spent on leisure and reduced their time in non-farm work, plausibly from more productive supply of labor, less requirement to supplement household budget and/ or social norms. Credit has increased labor supply (Fink et al., 2020) while transfers have reduced women's probability of working and increased men's participation in domestic chores (Hidrobo et al., 2016; Beaman et al., 2023; El-Enbaby et al., 2025). Programs directly impacting agricultural productivity, such as the System of Rice Intensification, caused women to reallocate labor from non-farm activities into rice cultivation in Indonesia (Takahashi and Barrett, 2014).

Governments in developing countries routinely provide agricultural loan subsidies or collateral-free credit to encourage investment among small and marginal farmers. The effects on household welfare, and on individual members in particular, remain understudied, a gap made more important by the mixed evidence on agricultural outcomes (Karlan et al., 2014; Tarozzi et al., 2015; Maitra et al., 2017; Nakano and Magezi, 2020; Fink et al., 2020; Beaman et al., 2023; Mukherjee et al., 2024). This paper builds on Xu et al. (2026) which analyzes the effects of the credit program on borrowing, agricultural outcomes and perceived stress among borrowers. Our findings on how the collateral-free loan program affected household members generates an important policy implication: household-level interventions in joint production structures can be utilized as an effective way to improve women's outcomes while avoiding the pecuniary and social costs of targeted programs. This is critical for development finance institutions and governments that are actively trying to scale up such products in low-and-middle income countries.

2 Theoretical framework: Loan and Individual Welfare

The agricultural sector in India is well-suited to test the indirect effects of a household-level intervention on its members because production involves joint contributions by household members on the same plot. The Indian Ministry of Agriculture & Farmers Welfare formally recognizes this joint production system, classifying agricultural land managed by multiple members of the same household as "individually operated". Doss (2018) documents that it is difficult to separate individual contribution to and profits from agricultural production. Targeting agricultural credit to women in multi-adult households, therefore, may not guarantee an improvement in women's control over resources. In this section, we outline how household members are potentially affected by a program that targets the household's liquidity constraints.

One pathway through which household credit can affect its members is the intensifi-

cation of household production, which could change the household's demand for labor. We describe stylized facts below that rule out agricultural intensification as the main channel, allowing us to focus on the effects of reducing household liquidity through the consumption channel. We also expect that the loan product increased household members' engagement with digital financial services as it allowed digital repayments.

Stylized Fact 1. *The loan product increased household consumption of composite goods.*

Bobonis (2009) characterizes a household's consumption as public, private and "composite", where composite goods are consumed both individually and jointly by household members. We find increased accumulation of composite goods in our setting through farm and business equipment and consumer durables. We report estimates of a formal test in section 5.1.

Stylized Fact 2. *The loan product did not change a household's spending on wages or other inputs.*

In our sample, we find no detectable changes between treatment and control villages in the wage rate paid for hired labor, spending on other inputs, or real farm income.[1] There were also no differences in the total number of days worked by family members over the season. We therefore rule out the agricultural intensification channel in theorizing impacts of the loan on household members.

We now theorize impacts on household members taking these stylized facts into account. We utilize the collective household model, in which household members have distinct preferences (Chiappori, 1992), and extend the framework in Bobonis (2009) that characterizes household consumption as private, public and composite goods. This lets us identify the loan's effect on individual household members through both household-level and private consumption channels, and test the impacts on women and men separately.[2]

Appendix A describes the full set up of our static model of household and individual decision making in response to the loan. We consider a two-member household where each member has distinct individual preferences and earns a labor and non-labor income. Each individual derives a positive utility from household consumption of public and

[1] Estimates are reported in Appendix C. Section 5.2 discusses the results on farm input use and income alongside the results on household members' labor supply, and relates them to the findings of the companion paper (Xu et al., 2026), which evaluates the impact of the loan program on borrowing and agricultural production.

[2] A unitary model assumes that a household's use of the loan would not depend on which member is the beneficiary of the product (Samuelson, 1956), the household has a single decision maker and household members have homogeneous preferences. Such a framework would not allow us to measure the indirect utility response for household members where household consumption increases but their residual income falls.

composite goods, as well as from their own private consumption, leisure and financial autonomy. Composite goods include consumer durables and productive assets such as farm and business equipment. Unlike consumer durables, productive assets can also affect household output and the household's demand for members' labor. The total household budget is a sum of labor and non-labor income as well as joint non-labor income. The following assumptions are relevant to our research questions and testable hypotheses.

Assumption 1. *The household treats the loan as an increase in joint, non-labor income in the short term.*

Assumption 1 reflects the organization of farm production at the household level, which makes a loan for farming likely to be treated as a joint resource. The program design is consistent with this, since two household members co-signed the loan (Section 3.3). The static model captures household decisions in the short term when the loan expands the household budget. Although most loans were repaid before the endline survey, the composite goods acquired by the household, such as farm equipment and consumer durables, remained with them and so endline outcomes reflect these purchases (Stylized Fact 1).

Assumption 2. *Financial autonomy and leisure are normal goods for each household member.*

We define financial autonomy as a member's independent access to and use of financial services. If the loan raises a member's residual income, normality implies that they exercise more financial autonomy and consume more leisure. Stylized Fact 2 shows that the loan did not change the household's use of farm inputs, including family labor days, or farm income. Changes in members' time allocation are therefore unlikely to reflect changes in demand for labor in farm production. This inference does not extend to labor demand for non-farm activities.

We set up the household optimization as a two-stage problem in Appendix A that distinguishes the loan's effects on household-level and individual-level consumption (Blundell et al., 2005; Bobonis, 2009). In the first stage, given the household budget, which includes the loan amount, the household chooses expenditure on the public and composite goods. The bargaining weight depends on individual and joint incomes and on a non-monetary distribution factor that affects bargaining power without entering preferences or the budget constraint. In the second stage, conditional on allocations to public and composite goods, each member chooses private consumption, leisure and financial autonomy to maximize utility subject to an individual residual income constraint. The individual residual income is the difference between the total earnings and contributions to household consumption. Each member's contribution to household consumption is

determined by a sharing rule that depends on the bargaining weight and total household resources.

We show that the indirect utility of an individual in response to the loan can be decomposed into the change in utility from increased consumption of public goods, composite goods and changes in their residual income. The loan can change the individual residual income in the short term in two ways. One is a bargaining channel, where if the loan shifts the bargaining weight in a member's favor, their required contribution falls. The other is the resource expansion channel, where, holding the bargaining weight fixed, the household can finance joint expenditure from the loan rather than from members' own earnings, reducing their required contributions. A member's residual income rises whenever their required contribution falls.

2.1 Testable predictions

We analyze first-stage changes in household consumption of composite goods through the ownership of farm and business equipment and consumer durables, and report the household's food consumption score as an additional household-level outcome. In the second stage, we do not directly observe individual residual income, but interpret its effects through members' financial autonomy measured as the independent use of debit cards and mobile apps for banking, and through time allocated to personal activities, farm work, and non-farm work. We test for the resource expansion channel affecting individual residual income through self-reported account activity such as deposits, and the bargaining power channel through their self-reported involvement in decisions on production and consumption.[3] Productive assets can also change the household's demand for members' labor, however, we observe only the aggregate labor response, which is net of changes in labor demand and the increase in leisure.

3 Experimental Design and Data Collection

3.1 Context

This intervention was conducted in two districts in India: Jajpur in the state of Odisha and Amravati in Maharashtra (Figure 1). Farmers in Jajpur mainly grow rice, while those in Amravati grow cotton and soybean. Both groups face credit constraints, based on reports from our implementation partner Dvara E-Registry (DER), a fintech company.

[3] We also asked respondents their income shares from farm and non-farm work to test whether women's involvement in decisions on their private consumption is influenced by the share of their income from non-farm work; however, this question was not administered correctly by the enumerators.

The loan program targeted small and marginal farmers[4], which constitute the majority of agricultural holdings in both states.[5] The rice crop in Odisha is transplanted June through July and harvested in September through November. The agriculture sector in this state employs more than 70% of rural women, most of whom are engaged in rice farming (Barooah et al., 2025). Women almost exclusively perform nursery preparation, transplanting, weeding, harvesting, and threshing. Weeding is done manually or with simple hand tools. Cotton is sown in Maharashtra from May to June and harvested between October through December. Women in Maharashtra are responsible for the majority of on-field tasks of cotton cultivation such as sowing seeds, stalk removal, ensuring optimum plant population, weeding, fertilizer application, and picking (Dwivedi and Damle, 2019). Men are primarily responsible for operating machinery (tractors, ox-carts) and for managing market and sales transactions. Soybean is sown June- July and harvested September through October. For soybean, women perform the more labor-intensive manual tasks including weeding, loosening soil, and seed preservation, while men handle ploughing, marketing, and machine operations.

The major constraints to credit access in our study locations include expensive interest rates and the absence of a land title. The main sources for formal credit include commercial banks (government or privately owned), small finance banks (private sector entities servicing small and marginal producers), microfinance institutions (MFIs), cooperatives, self-help groups (SHG) and registered entity of producers that share profits called farmer producer organizations (FPO). Interest rates of loans offered by MFIs and small finance banks vary from 18 to 26% in Odisha and are about 24% in Maharashtra. Loans supplied by commercial banks have lower interest rates but require a collateral and documents that many households cannot provide. They also delay loan approval and disbursement well beyond the planting season when farmers need cash on hand to buy inputs. Loans from SHGs and FPOs do not require collateral for members but are available on rotation and not every planting season. The Indian government offers a collateral-free loan of up to INR 200,000 (about USD 2,250) to farmers called the Kisan Credit Card (KCC) at the maximum interest rate of 7%, however, it is restricted to farmers that own land. This makes majority of our sample ineligible as we show in Table 1. Figure C.1 shows that fewer than 20% of farmers in our control group reported taking the KCC loan in the endline survey.

[4] Small farms are plots of size 1-2 hectare and marginal farms have plot sizes less than 1 hectare.
[5] The Agricultural Census 2015-16 classifies over 30% of landholdings in Odisha and Maharashtra as small. Marginal holdings account for 45% of landholdings in Odisha and 18% in Maharashtra.

3.2 Randomization

We draw from an experiment designed by the International Food Policy Research Institute (IFPRI) and implemented by Dvara E-Registry (DER), that evaluates DER's KhetScore credit-scoring approach through two cluster-randomized trials. In this paper, we evaluate the impacts of the loan intervention arm from the second trial on household consumption and individual members.[6] We do not analyze a third intervention arm of this RCT that provided loan and insurance bundles because 15 out of the 20 study villages in that arm were already exposed to the same credit and insurance bundle through an earlier program. The timing of our evaluation does not let us analyze the exogenous and unanticipated impacts of credit access in these villages.

The sample includes 80 villages identified by DER, 40 in two blocks of Jajpur district (Odisha) and 40 in four blocks of Amravati district (Maharashtra).[7] Between September and October 2022, DER held a meeting in each village, scheduled with village heads to ensure farmers could attend. The meetings covered credit options available in the market, and DER did not elicit applications, describe its loan product, or provide information that could shift norms around borrowing, mobile phone use, or financial autonomy. A roster of at least 20 farmers per village was compiled from meeting participants.

After meetings had concluded in all villages, villages were assigned by lottery to treatment or control, with 20 villages per arm in each state. In Odisha, 29 of the 40 villages were randomly drawn from the control group of an earlier evaluation of a credit and insurance bundle (Kramer et al., 2025): 15 were assigned to treatment and 14 to control through the lottery mentioned above. None of these villages had previously been offered DER's credit products, and, like all control villages, they had access to formal and informal credit in the market.

3.3 Loan program and Eligibility

DER offered a collateral-free loan to small and marginal farmers by partnering with one commercial and one small finance bank. DER provided these loans in the summer planting season in 2023 and the winter season spanning 2023-24. In this paper, we only analyze the impact of credit provided in the summer planting season as the timing of the endline survey captures the repayment from this season. It also avoids the confounding effects of

[6] A companion paper, Xu et al. (2026), tests the households' uptake of both credit and insurance, indebtedness, costs and revenue from production for the credit arm as well as the credit bundled with insurance arm in the second trial. Kramer et al. (2025) evaluates the first trial.

[7] Blocks are administrative sub-divisions of districts used for rural planning and development, and may share the district's name. The sample includes Dashrathpur and Jajpur blocks in Jajpur district, and Amravati, Ashti, Morshi, and Tiosa blocks in Amravati district.

anticipation of the product. Additionally, most farmers in the surveyed regions did not cultivate during winter. The loan amount ranged between INR 30,000 and 60,000 (USD 330 and 660), varying by the size of the land, and majority of the farmers were offered INR 30,000/ USD 330. It was offered at the beginning of the planting season and farmers repaid the loan in monthly installments by crash or mobile apps.[8] The option to repay through a digital platform may also have increased household members' knowledge and use of digital financial services directly. The program addressed two additional challenges to credit access for these farmers - loan application and processing times. DER agents visited farmers at their field or home and filled out the application on their behalf. The loan was processed within seven business days for successful applicants. Only 3 of the 353 households that borrowed under this program defaulted, yielding a repayment rate of about 99%.

To be eligible for the loan, farmers were required to have attended the meeting organized in their village at the start of the intervention. Eligibility also required residency in the village for at least five years, farming on no more than three acres, and cultivation at least once in the past three years in the borrowing season. Their creditworthiness was computed by DER using an innovative approach that utilized remote sensing data on crop productivity, farm area, damage from natural calamities or other factors, soil moisture and irrigation availability, soil nutrients and vegetative growth from the last three years. This weighted index is called KhetScore. Loan applicants were expected to have a KhetScore (or credit score) above 40. Figure C.2 shows that almost all the farmers in the study were above this threshold. Evaluations from established credit bureaus were additionally assessed when available.

Program costs and net returns per farmer

The program included fixed costs such as project management costs, field office and other materials that are listed in Table D.1. Costs that varied by farmer included the calculation of each farmer's credit score, engagement of field staff and discretionary allowances. It resulted in earnings of USD 63-72 per farmer. Subtracting total costs per farmer from the total revenue through interest payments yielded a profit of about USD 13 and 23 per farmer in Odisha and Maharashtra, respectively.

3.4 Data collection and Attrition

Baseline: The survey was conducted between November 2022 and February 2023 by an independent team of enumerators hired and trained by the International Food Policy

[8] The implementing partner reported that farmers expressed preference for a monthly repayment plan over lump sum payment after harvest.

Research Institute (IFPRI). The enumerators interviewed the farmer who attended the information session. The questionnaire included detailed information about the crops cultivated during the summer and winter agricultural cycles, inputs utilized in cultivation, asset ownership, economic shocks, dietary diversity and participation in decision making. Across the 80 villages, the goal was to interview approximately 21 households per village and the baseline data included 1,682 households.

Administrative data: We utilize DER records on the number of households that applied for a loan in the treatment arm, were successful and the loan amount they received during the summer of 2023. We also analyze the credit score estimated by DER in 2023 for each household our sample.

Endline: The endline survey, conducted again by IFPRI with the help of an independent team of enumerators between April and August 2024, successfully re-interviewed 1,431 households from the baseline. The survey was expanded to interview two members of each household: the farmer who had attended the information session before baseline (henceforth, the "panel respondent") and one additional household member, oftentimes their spouse or the most informed available household member. This second member was successfully interviewed in 1,066 households. We expanded the modules from the baseline survey to also measure respondents' financial autonomy and their time use (see Appendix B for a description of all variables).

Sample size and Attrition: There is 15% attrition between the baseline and endline surveys and the sample is balanced across the intervention arms (column 1, Appendix Table D.2). Column 2 of the same table shows that households' ex-ante characteristics are generally uncorrelated with attrition, with two exceptions: households with a female panel respondent were more likely to drop out of the sample, and those with an outstanding loan were less likely to do so. We omit two households where the respondents were recorded as below 18 years of age. This gives us a balanced panel of 1,429 households that includes 1,061 other household members.

We report household and panel respondent characteristics from the baseline survey in Table 1. Column 2 and 3 also report averages for treatment and control groups, respectively. Households in both intervention arms were statistically similar on observables before the loan program was implemented. The average respondent interviewed in baseline was middle-aged (about 43 years old) and over one-third were women. Less than half (47%) of the households owned land and, therefore, ineligible for the government's credit program. Borrowing is prevalent - over 40% of the sample took a loan in the 12 months prior to baseline survey, and one in five households had an outstanding loan. Over 90% of the panel respondents had a bank account.

4 Estimation

4.1 Intent-to-Treat

We estimate the intent-to-treat (ITT) effect of the loan intervention on household resource allocation using the ANCOVA model below. This exploits the random assignment of the intervention and a balanced panel of household outcomes and covariates measured using the baseline and endline surveys.[9]

$$Y_{hvb,1} = \alpha_0 + \alpha_1 Y_{hvb,0} + \alpha_2 TREAT_v + \sum_{j=1}^{J} \theta_j \mathbf{X}_{jhvb,0} + \eta_b + \tau_m + \epsilon_{hvb} \quad (1)$$

Equation 1 estimates the effect of the program on household-level outcomes, indexed by h, controlling for their baseline values, $Y_{hvb,0}$. Appendix B describes these variables. Table D.4 shows that outcome variables are balanced between treatment and control groups at baseline, with the exception of total expenditure on hired labor.[10] We control for household covariates described in Table 1 as well as features of soil quality including moisture, nutrient and productivity that were used to determine each plot's creditworthiness in $\mathbf{X}_{hjvb,0}$.[11] The binary indicator $TREAT_v$ identifies villages v in the treatment (= 1) and control arms (= 0) and coefficient α_2 estimates the ITT effect of the intervention on outcome $Y_{hvb,1}$. We include block fixed effects (η_b) because treatment was stratified by block, an administrative aggregation of villages, and the fixed effects also control for differences in markets and institutions. Any differences in recall due to survey month of the baseline and endline are controlled for using month fixed effects (τ_m). There are 80 villages in the sample and standard errors are clustered by village, which is the level of treatment assignment. We report sharpened q-values (Benjamini et al., 2006; Anderson, 2008) which control the false discovery rate, as a correction for multiple hypothesis testing within each family of outcomes. The family of outcomes are specified in all results tables.

4.2 Local Average Treatment Effect

We analyze the local average treatment effect of the loan on individual-level outcomes using an Instrumental Variables (IV) model. The first stage tests the predictive power

[9] We do not reweight observations using inverse probability attrition weights as Table D.2 shows that attrition is balanced across intervention arms.

[10] To assess impacts on household labor demand, we use the real wages households paid for male and female labor, which are balanced at baseline.

[11] We report estimates conditional on all covariates as there are very small differences in the magnitude of treatment effects when only a subset of covariates identified by post-double selection LASSO method (Belloni et al., 2013) are included.

of the exogenous assignment of loan treatment, $TREAT_v$, to households h taking up the loan for cultivation in summer of 2023. The endogenous variable of loan take up is defined using administrative data from DER and described in Table D.3.

$$ReceivedLoanProduct_{hv} = \beta_0 + \beta_1 TREAT_v + \sum_{j=1}^{J} \theta_j' \mathbf{Z}_{jihvb,0} + \eta_b + \mu_{hv} \quad (2)$$

Table 2 reports that households were 48.1 percentage points more likely to apply for and received the loan. We refer to treatment households that applied for and received the loan as borrower households. The F statistic is 151, above the conventional threshold of 10, and the instrumental variable explains approximately 30% of the residual variation in loan take-up after partialling out baseline covariates and block fixed effects. The equation below is the Two-Stage-Least-Squares (2SLS) estimation of the instrumented variation of a borrower household on outcome variables.

$$Y_{ihvb} = \gamma_0 + \gamma \widehat{ReceivedLoanProduct}_{hvb} + \sum_{j=1}^{J} \theta_j'' \mathbf{Z}_{jihvb,0} + \phi RespType_{ihvb} + \eta_b + \upsilon_{ihvb} \quad (3)$$

We analyze outcomes for female and male respondents separately using this 2SLS model and test the equality of women's and men's coefficients by comparing estimates from the two samples.[12] We control for household characteristics from the baseline survey described in Table 1 in $\mathbf{Z}_{hjvb,0}$ and also control for respondent's age and marital status in the endline survey as this information was only captured for the main respondent at baseline. We also control for whether the respondent is the panel respondent or the other household member ($RespType_{ihvb}$) in equation 3. We include block fixed effects (η_b) and cluster standard errors by village. Estimates of time use also include survey month fixed effects to control for seasonal differences in the respondent's recall of their time allocation. We adjust p-values for multiple hypotheses testing by reporting sharpened q-values.

The model satisfies the following key assumptions of an IV model. First, we satisfy in Table 1 that the treatment assignment is exogenous by verifying that households' observable characteristics are balanced at baseline between the treatment and control arms. Table D.2 shows that attrition of households does not differ by treatment status.[13] Second, the exogenous village level treatment assignment positively affects a household's take up of the loan product (Table 2). Third, the village meetings did not share information that could impact preferences for loans, social norms on financial autonomy and

[12] This is an approximate test given respondents are drawn from the same households and villages, and their estimates are likely correlated.

[13] Nearly all baseline characteristics are uncorrelated with attrition, except for households with a female panel respondent were 6 pp more likely to drop out of the sample and those with an outstanding loan were 6 pp less likely to do so. Treatment coefficient remains insignificant.

leisure or involvement in decision making. Fourth, we verify implementation fidelity in Table D.3 showing that only households in the treatment arm received the loan product. Finally, any household that met the eligibility criteria listed under section 3.3 could apply for and receive the loan. By this rule, one household's receipt of the loan product did not affect the likelihood of another household in the treatment arm receiving the product.

Since no control household received the loan, the LATE identifies the effect of treatment on the treated and is our main estimand for measuring impact on individual outcomes. We report ITT estimates alongside the LATE estimates of individual-level outcomes in section 5.2 as a robustness check that captures the effect of village assignment to treatment regardless of loan take-up.

5 Results

5.1 Household responses to the loan program

In this section, we provide empirical evidence for Stylized Fact 1. The intervention increased the ownership of productive capital and consumer durables by households in the treatment group relative to the control group. Table 3 shows a 13.8 pp increase in the ownership of farm equipment such as hand tools, animal-drawn plows and non-mechanized irrigation tools in the treatment arm relative to the control. Ownership of non-farm business equipment increased by 7.1 pp.[14] Households in the treatment arm were 7.8 pp more likely to own large consumer durables. This includes time-saving kitchen appliances such as refrigerators, televisions, and washing machines as well as other household durables such as sofa, dining tables, chairs, mattresses, cots or beds and computers. Relaxing liquidity constraints allowed households to purchase composite goods that may have been unaffordable without the loan. Because over 99% of loans were repaid, households ultimately financed these purchases from their own resources. We don't find increases in mechanized farm inputs such as tractors, electric pumps, seeder and threshers because even with subsidies from the government, some of these equipments cost at least four times more than the loan amount.

We find relative improvements (about 17%) in the diet quality of the households in the treatment group in Table 4. Panel A measures household dietary diversity using a 7-day recall measure of 8 food groups designed by the World Food Programme.[15] We

[14] Non-farm business equipment includes any equipment used in an enterprise unrelated to farming. The survey listed solar panels used for recharging and sewing machines as examples, but respondents could report other equipment meeting this definition.

[15] The score assigns the following weights (in parentheses) to different food groups: Cereals, grains, roots and tubers (2); legumes/ pulses, nuts and seeds (3); milk and other dairy products (4); meat, fish and

further analyzed whether the individual respondent consumed the same food groups in the last 24 hours in panel B, weighting responses in the same manner as the household food consumption score with frequency 1 (one day). Both women and men's food consumption in the last 24 hours was significantly higher in response to the loan program.

5.2 Impact on household members

Having estimated the household response to the loan, we now report changes in individual level outcomes for female and male household members in our sample. We focus primarily on the interpretation of women's outcomes given the focus of this paper, and discuss how they relate to the impacts on men where relevant.

Financial Autonomy

Table 5 shows that the loan product did not impact women's preference for having their own bank account, but they report greater access to resources. Women (men) in borrower households were about 40 pp (34 pp) more likely to deposit funds that were not earnings or transfer payments in their account suggesting increase in their residual income through the resource expansion channel. We find direct impacts on their financial autonomy through debit card use. Women in borrower households were 70 pp more likely to report that the debit card linked to their account was only used by them. Men in borrower households were 14 percentage points more likely to hold an individual account than men in the control group. This is possibly explained by 68% of loan recipients in the treatment arm being men, many of whom may have opened an individual account to receive the loan. Distinguishing men and women as independent sample, the equivalence tests of the estimates are not statistically significant. Men also reported greater likelihood of using their debit card autonomously in response to the loan. Both LATE and ITT estimates are significantly larger in case of women than men and likely driven by differences in the control group mean: fewer than 20% of women in the control arm used their debit card independently, compared with roughly half of the men.

Women were over 80 pp more likely to have knowledge and experience using mobile banking apps in borrower households relative to the control group (Table 6). The increased engagement in digital financial services is a second source of enhanced financial autonomy as these apps increase a user's privacy in transactions. Men in these households also exhibited greater engagement in mobile based transactions than the control group (43 pp more likely to have knowledge and 37 pp use). Women in borrower households reported greater mobile phone ownership (over 13 pp but not statistically significant) rel-

eggs (4); vegetables and leaves (1); fruits (1); oil, fat and butter (0.5); sugar and sweets (0.5); condiments (0).

ative to the control group. Among women with their own bank account, comprising 83% of the sample, the difference in mobile phone ownership was statistically significant (24 pp, LATE estimate and 12 pp, ITT). The effects on knowledge and use of mobile banking apps were also larger for these women than for the full sample. We treat these estimates as descriptive since both individual-level bank account and smartphone ownership were measured at the endline. The intervention did not appear to explicitly change household take-up of smartphones as about 74% of households owned at least one smartphone at baseline, and there were no changes on the extensive margin between the treatment and control groups over time. Equivalence tests of the coefficients of knowledge and use of mobile banking apps show that the treatment effects for women are significantly larger than those for men, again owing to a smaller control group mean for women. This indicates that the loan product narrowed gender gaps in knowledge and use of mobile banking. Finally, we show that the positive impacts on financial autonomy are consistent across both states in our sample in Tables D.12 and D.13.

The positive impact of the loan product on women's uptake of digital financial services is noteworthy, since women's internet access have been persistently low in India owing to rigid gender norms (Barboni et al., 2018). The results on increased engagement in mobile apps for banking, largely explained by the expansion of women's access to resources in borrower households, contrast with the findings of Barboni et al. (2024) where smartphone provision to rural women in Chhattisgarh led to no impact on women's knowledge or use of mobile banking. Instead, they found that 40% of the women transferred their phone to another household member, highlighting that targeted asset provision doesn't guarantee resource control.

Time use

We asked women their time allocation across different production and consumption activities listed in Table B.1 to test implications of the loan on individual labor supply. Table 7 shows that women in borrower households spent about 0.94 (53%) more hours on personal activities such as visiting friends, watching TV etc., than the control group (mean = 1.68 hours) during the busiest day of the past agricultural season. This result suggests an income response to increase in residual income as leisure is a normal good in our theoretical expectations. Time allocations across activities do not add upto 24 because respondents were asked the time they spent on activities in Table B.1 conditional on them reporting they participated in that activity. Appendix B explains the structure of the survey module.

Women in borrower households allocated about 2.3 hours less on farm activities than

women in the control group (mean = 3.1 hours) on the busiest day in the agricultural season, however, this reduction is not representative of the entire season. Table D.7 shows that the number of days worked on the farm in the past agricultural season is not significantly different for female household members between the treatment and control group as recalled by the panel respondent.[16] Women's reduction of hours to farm work on the busiest day is consistent in the ITT estimates (1.9 hours in treatment versus 3.1 hours in control group). If the panel respondent recalls household members' labor supply correctly, the results imply that although women significantly reduced the number of hours they allocated to farming activities in a day, their contribution in terms of the number of days worked over the season did not differ significantly between the treatment and control groups.

Despite women allocating fewer hours to farm activities in the treatment group relative to the control group, Table D.8 shows there were no impacts on real farm income[17], total quantity harvested and yield. One explanation for the reduction in farm hours in a day is that households' ownership of non-mechanized farm equipment allowed women to work more productively. As described in section 3.1, women are primarily responsible for manual tasks such as transplanting, weeding and picking while men operate machinery and perform market-facing activities. Additionally, in Table D.9, we report no significant differences in households' payment of real wages to male or female hired labor. There were also no relative changes in households' expenditure on *other inputs*[18] such as irrigation, purchase of seeds and fertilizers or renting of machinery and land (Table D.10) that may have enhanced the demand for farm labor.[19] Men's time allocation to farm and non-farm production on the busiest day of the agricultural season remained statistically similar between borrower and control group households, lending support to the productivity enhancing channel for women.

Women also reported a reduction in time spent on non-agricultural work such as self

[16] We observe seasonal labor supply, farm income, yield, and household input use in both the baseline and endline surveys, therefore, we estimate effects on these outcomes using the ANCOVA model, which compares treatment and control groups at endline while controlling for baseline values of the outcome.

[17] Our estimates of Kharif crop sales revenue differ from those in Xu et al. (2026) in sample, measurement, and specification. We use the balanced panel of households in credit-only and control villages, value each crop's sales at the unit price reported by the household, sum over all crops cultivated, and express revenue in 2022 rupees using consumer and wholesale price deflators. The companion paper uses the full study sample by state, values sales at a reference price for a state-specific set of crops in nominal terms, and controls for a different set of baseline characteristics. Xu et al. (2026) find that the loan increased cultivated area, revenue, and profit in Odisha, with limited effects in Maharashtra.

[18] This result is robust to households' use of *any formal loans*. Table D.11 shows that the treatment group did not utilize loans to finance spending on seeds, fertilizers, labor or renting machinery.

[19] These results apply to the balanced sample analyzed in this paper. We use a balanced panel of households as attrition is balanced across the treatment and control villages.

employment or wage employment on both the busiest day of the agricultural season. Since ITT estimates of differences between the treatment and control groups are consistent, we explore the corresponding accumulation of business equipment by households in the treatment villages relative to the control as a possible productivity-enhancing explanation, however, we do not have corresponding income or output measures to verify. The large point estimates of reduction in hours worked indicate a significant reduction of women's participation in non-agricultural work on the extensive margin. This may be the result of households relying less on small businesses to meet their budgetary needs after receiving the loan. Table D.6 shows that among women who did participate in the activity, in borrower households, they allocated significantly more hours towards non-agricultural work (2.1 hours) and less towards domestic work (0.95 hours) in the day before the survey. We interpret these estimates cautiously because the sharpened q value is about 0.18 for these outcomes, which allows 18% of false rejections in each set (busiest day and day prior to survey).

We examine whether women's perceptions of gender roles bias their time-use reports as a robustness check. In this test, we assume that women who have their own bank account are less affected by any social biases around women's economic participation and may provide more accurate reports of their time allocation than women who don't. To the extent that this captures women's insulation from social norms, we find no heterogeneous effects of women's time allocation to farm or non-agricultural work by independent bank account ownership in Tables D.15 and D.16.

Men's economic participation remains statistically similar between the borrower households and the control group. The ITT estimates of all time use results are consistent with the LATE estimates for both women and men. Time allocation on the day before the survey follows the same patterns as on the busiest day of the agricultural season, with one exception. Women in borrower households report significantly fewer hours of domestic chores than the control group on the day before the survey, whereas the corresponding estimate for the busiest day is not statistically significant.

We examine women's time allocations by state given differences in the crops planted and production processes across the two states. Tables D.17 and D.18 show that the reductions in economic participation are driven by households in Maharashtra and greater allocation to leisure by Odisha. Households' report of farm labor supply by members over the season, expenditure on labor (real wages and total real spending) and real income from farming are not significantly different between the treatment and control groups in either Odisha or Maharashtra (Tables D.19-D.21), validating that any reduction in

farm labor on the busiest day in the agricultural season is not consistent over the season. The pattern of women's reduction in non-farm work in Maharashtra and greater time allocation to leisure in Odisha is possibly the result of differences in social norms between the two states. Maharashtra is systematically more conservative in gender norms than Odisha. It matches the findings in El-Enbaby et al. (2025) where women in rural Egypt reduced non-farm work but not their participation in agriculture in response to a cash transfer, consistent with greater social acceptance of women working for pay in agriculture than non-farm work in this setting.

Decision-making:
Finally, we investigate if there are potential impacts on individual residual income through changes in bargaining power measured as women's involvement in decision-making. Figure 2 reports LATE estimates for the share of decisions women participated in over the last 12 months, along with category-wise participation. The loan product did not affect the share of decision categories in which women or men participated, nor their involvement in any individual category on the extensive margin. The one exception is farming decisions, where women in borrower households were 21 pp less likely to participate than the control group (mean = 0.68), though the adjusted p-value exceeds conventional thresholds.

For decisions made jointly with their spouse (Table D.23), women in borrower households are more likely to participate in livestock and poultry management and household consumption, however, the sharpened q-value is 0.153, therefore, we interpret these results cautiously. There are no differences in men's reports of joint decision making with their spouse between borrower households and control group. In panel C, we restrict the data to approximate households where spouses were interviewed[20] and find that the the loan product did not differentially impact whether both spouses report joint decision making consistently. We therefore treat the overall pattern as one of no *aggregate* impacts on intrahousehold bargaining power.

The empirical evidence of targeted programs on women's decision making is mixed. Cash transfer programs have had success (de Brauw et al., 2014; Bergolo and Galván, 2018) while social protection programs and bank account ownership did not (Roy et al., 2015; Field et al., 2021; Chauhan, 2025). Other financial inclusion interventions such as microfinance, savings groups, business loans and grants have had limited impact on

[20] These are households where two members were interviewed successfully in the endline survey. We further assume that the respondents are spouses in cases where either the woman interviewed was upto 19 years younger than the man (95th percentile of the distribution of age difference) or the man was upto 6 years younger than the woman (25th percentile).

women's decision making ability (Banerjee et al., 2015; Karlan et al., 2017; Angelucci et al., 2015). Women's initial bargaining power in the household drives differences in program impacts in some contexts (Hidrobo and Fernald, 2013; El-Enbaby et al., 2025). We, therefore, investigate this mechanism in the next section.

6 Mechanisms

In this section, we examine potential factors that could impact individual welfare such as ex-ante measures of households' wealth, socio-economic identity and spousal coordination.[21]

Ex-ante wealth and socio-economic identity: We construct a wealth index using principal component analysis of the assets owned by a household at baseline and classify all households in our sample by quintile of this index. Interacting this categorical variable with the instrumental variable for whether households took up the loan shows no significant correspondence with women's or men's bank account or smartphone ownership, use of debit card and engagement with mobile apps for banking. Table D.26 shows that in wealthier households that borrowed under this program, women spent less time on household purchases and domestic chores than in the control group on the busiest day of the agricultural season. These results are statistically significant with 10.7% chance of false rejection after adjusting for multiple hypotheses testing. Men in wealthier borrower households, also spent less time on household purchases, and allocated more time to personal activities such as leisure. The heterogeneity in time allocation by women does not persist in the day prior to the survey. However, Table D.27 shows that wealth drives fewer hours spent by men in livestock and poultry management and more hours in personal activities on the day prior to the survey. Table D.28 reports no heterogeneous effects by asset quintile on women's and men's involvement in decision-making with the exception of men in wealthier households relatively less likely to participate in household consumption decisions, consistent with their time allocations on the busiest day of the agricultural season to this activity.

Households belonging to Scheduled Caste (SC) and Scheduled Tribes (ST) are historically more disadvantaged, therefore, we investigate if the loan impacted SC/ ST households differently from the rest in Tables D.29-D.33. We find no heterogeneous effects in the individual-level outcomes with the exception of women in borrower households that identified as SC/ ST were more likely to know how to use mobile apps for banking, relative to the control group.

[21] We estimate the heterogeneous treatment effects using 2SLS. Loan take-up and its interaction with a baseline covariate are treated as endogenous and instrumented with village assignment to treatment and its interaction with the same baseline covariate.

Historically, households belonging to Scheduled Castes (SC) and Scheduled Tribes (ST) have been more disadvantaged, so we test whether the loan affected them differently in Tables D.29-D.33. We find no heterogeneous effects on individual-level outcomes, with one exception: among women, the loan's effect on knowledge and use of mobile banking were larger.

Ex-ante coordination between spouses: We estimate spousal coordination within a household using a continuous variable of the share of decisions on production and consumption activities that the panel respondent made with their spouse before the introduction of the loan program. While the loan did not change women's involvement in decision-making on average, it had a larger effect on decision-making in households where spouses were already coordinating more before the intervention. Table D.34 reports that women were more likely to be involved in decisions on non-agricultural work, household and private consumption, domestic chores and personal activities. There were positive heterogeneous effects on men's involvement in decisions on non-agricultural activities.

Greater ex-ante spousal coordination encouraged more time allocation to non-agricultural activities and household purchases for both women and men in borrower households relative to the control group during the busiest day in the past agricultural season (Table D.35). Women in these households also allocated relatively more time to domestic chores. In the day prior to survey, there were no heterogeneous effects on men's time allocation while women reported more time allocation towards non-agricultural work and domestic chores (Table D.36).

Table D.37 reports that ex-ante spousal coordination corresponded negatively with women's individual account ownership in borrower households, however, there were no differential trends in autonomous debit card usage or knowledge and use of mobile banking apps (Table D.38).

7 Selection into the program

In this section, we distinguish effects on women's agency by a household's selection into the loan program. Within the randomly selected treatment villages, households that attended the information session were offered the loan. These 702 households can be further split into 3 categories based on their loan application status - (i) applied and received the loan (352), (ii) applied but were unsuccessful (86) and (iii) did not apply for the loan (310). In Appendix Table D.39, we show that borrower households (category

i) were statistically similar in observable characteristics with households in the control arm. The unsuccessful loan applicants (category ii) had higher prevalence of literacy and bank account ownership than households in the control arm. However, these differences may be attributed to noise/ high sampling variability from a small sample size of 86. The households that did not apply for the loan (category iii) were less likely to have a bank account or have taken a loan in the year before the intervention than the control group. Half the households belonged to SC/ST. More than half of them were in the lowest income group captured in the survey (< USD 900 per year) and had lower schooling outcomes (35% of the panel respondents had completed secondary schooling vs. 50% in the control group).

Given these systematic differences within groups in the treatment arm, we follow Crépon et al. (2015) and estimate a propensity score of borrowing based on observable characteristics in the baseline survey (Figure C.3). We re-weight the LATE by each household's ex-ante predicted probability of loan receipt. The positive impacts on women's independent debit card use and both women and men's knowledge and use of mobile apps for banking are consistent in the re-weighted estimates reported in Tables D.40 and D.41. Men report a greater likelihood to share their debit card with other family members in borrower households than the control group. Women's time allocation of relatively more hours to personal activities and fewer to non-agricultural and farm work on the busiest day in the agricultural season were also consistent in Table D.42. Men reported spending fewer hours on livestock and poultry and more hours on domestic chores and personal activities. There were no aggregate differences in women or men's involvement in decision making with the exception of women reporting less likelihood to participate in decisions about farming and more in decisions on domestic work, however, adjustments for multiple hypotheses testing report very large false rejection rates.

The effect sizes of members' financial autonomy are smaller than results in section 5.2 indicating that borrower households experienced larger effects than the average likely borrower would.

8 Conclusion

This paper investigates whether an economic intervention at the household level can positively impact women's access to resources. We study this in the context of a collateral free loan to farming households in India. In contexts where household members participate in join production, such as agriculture in India, utilization of credit is unlikely to vary based on who is allocated the loan but can benefit individual members in two ways. First, if the loan raises the household's joint income in the short term and directly increases the

consumption of composite goods, such as productive capital and consumer durables that are shared or privately consumed, individual members' utility will increase from their consumption of composite goods. Second, individual members' residual income may change through a resource expansion channel or bargaining power channel which changes their residual income, resulting in a change in their private consumption and labor supply.

We study this using an RCT where a collateral-free loan was provided to small and marginal farmers in 40 of the 80 study villages in India. We combine the randomized loan provision with a balanced panel of 1,429 households interviewed in baseline and endline surveys. Households in both treatment and control groups were balanced on observable characteristics at baseline. We exploit the baseline and endline rounds to analyze the intent-to-treat effects of the loan program on household resource allocation using an ANCOVA model. We analyze the individual level outcomes collected in the endline survey and use a 2SLS model to estimate the local average treatment effect of the loan product on individual financial autonomy, time use and involvement in decision making. This model instruments the exogenous village-level treatment assignment for borrower households.

We report three main results. First, households increased their ownership of productive equipment for farm work (14 pp) and for non-farm business (7 pp), as well as large consumer durables (8 pp), and their dietary diversity improved by 17%. Second, women in borrower households report greater access to money. They were 40 pp more likely to receive deposits in their bank accounts two to three times a month. Alongside this expansion in resources, they exercised greater financial autonomy. They were 70 pp more likely to use their debit card on their own and over 80 pp more likely to know about and use mobile banking services. Third, women's time allocation shifted. On the busiest day of the agricultural season, women in the treatment group spent more time on leisure (2.6 versus 1.7 hours) and less time on farm work (0.8 versus 3.1 hours), although their labor supply over the season does not change. Farm income and yield are also unchanged, so the equipment may have allowed women to work more productively. Women also spend less time on non-agricultural activities such as business or wage employment, which may reflect lower demand for non-farm income after the loan. This decline is concentrated in Maharashtra, suggesting that social norms may also shape women's response. Finally, the loan did not change women's involvement in decisions on production or other activities, however, the loan reinforced existing cooperative household arrangements. Women in households with greater ex-ante coordination among spouses on decisions, were more involved in decision-making.

For policymakers, this evidence highlights the downstream welfare effects of agricultural support programs that aren't accounted for when evaluating their benefits. Women in rural agrarian households typically face limited financial access (Demirguc-Kunt et al., 2022) and there is a critical need for cost-effective, scalable programs that improve women's access to resources. By positively impacting women's independent use of financial services, such interventions extend benefits beyond farm productivity and income.

9 Figure

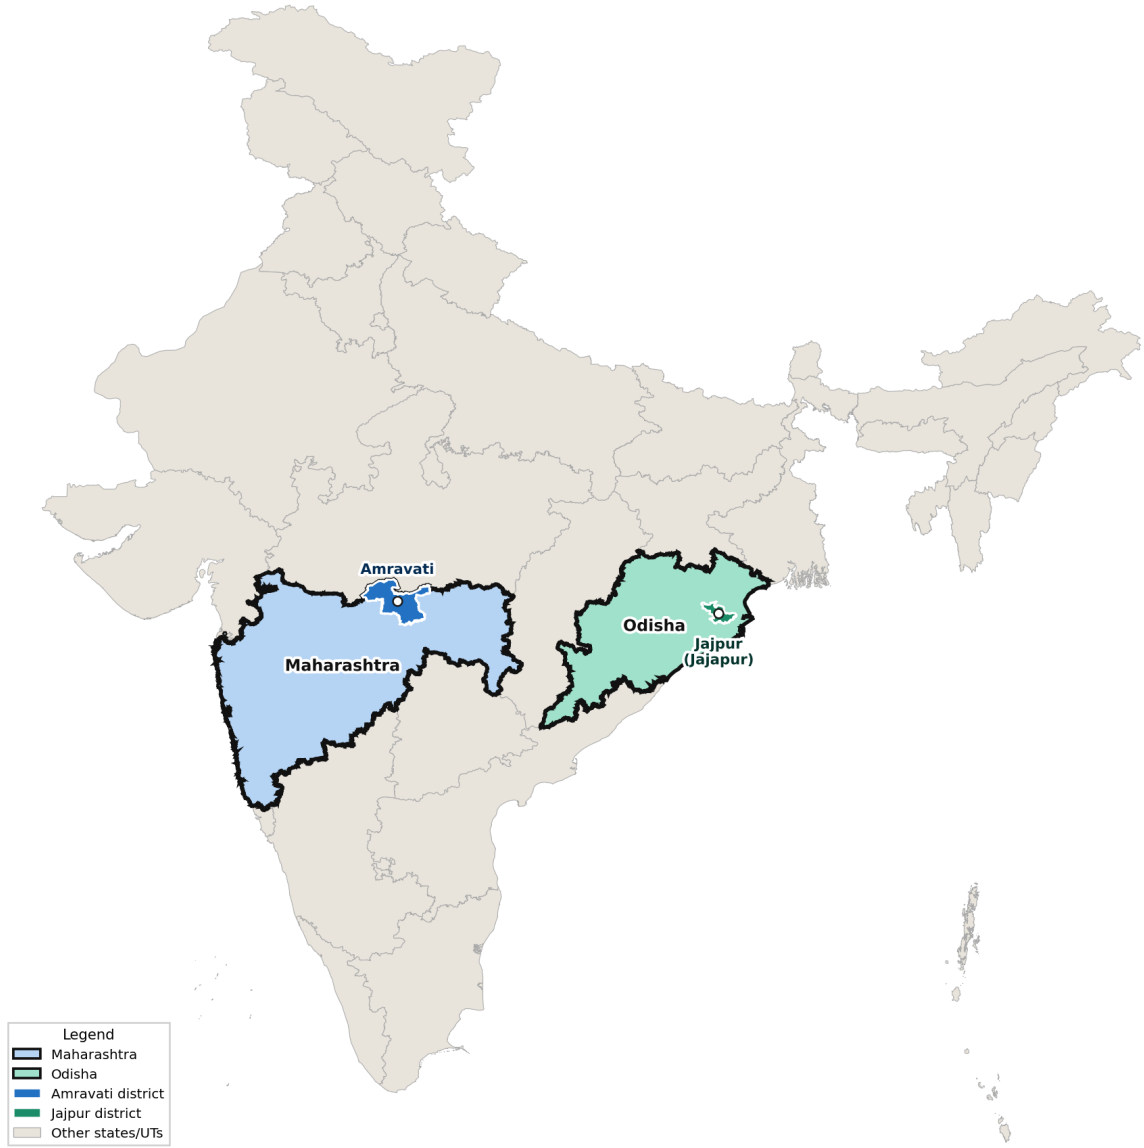

Figure 1: Study location

Notes: The figure indicates the two districts in India where the program was implemented - Amravati in Mahrahstra (blue) and Jajpur in Odisha (green).

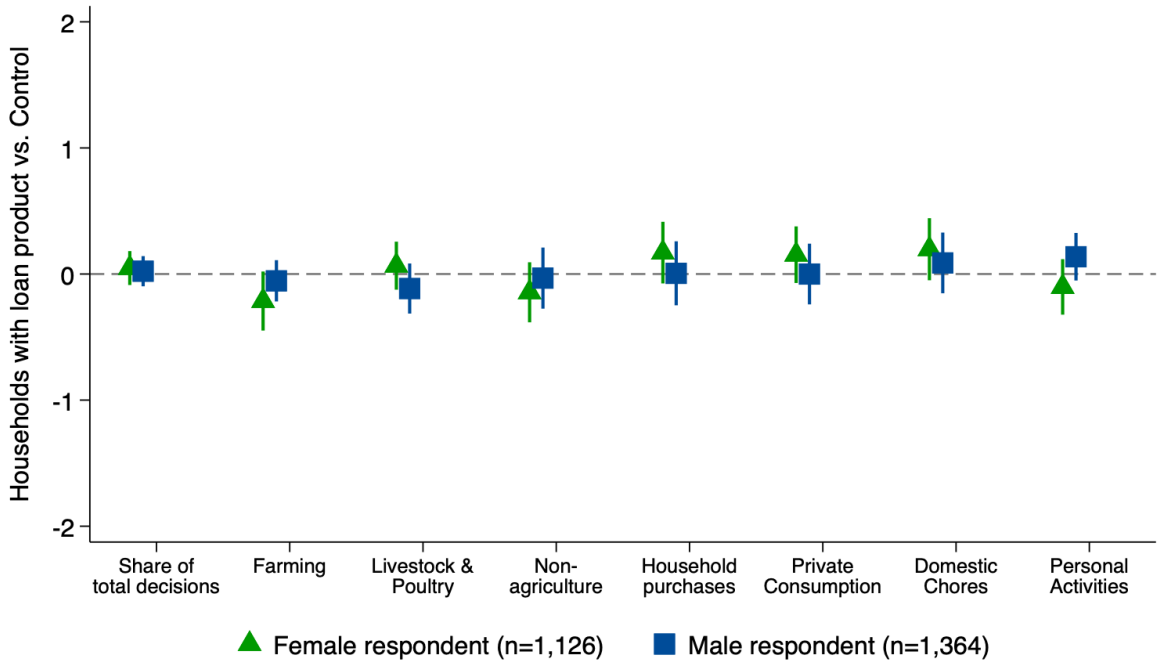

Figure 2: LATE: Loan intervention and involvement in decision-making

Notes: The figure the local average treatment effect of the loan on women and men's involvement in decision making on production and non-production activities (described in Table B.1). Sharpened q values report statistical significance of coefficients after correcting for multiple hypothesis testing. $*$ q$<$ 0.1, $**$ q$<$ .05, $***$ q$<$ .01. The p-value of an equivalence test is reported if the coefficients of men and women differ significantly from each other.

N	1429	748	681		

Notes: The table reports averages of respondent and household characteristics from the baseline survey by intervention arm. Column 1 reports pooled estimates for the full sample. Column 2 reports the averages for the loan treatment arm and column 3 for control arm. The fourth column reports the f test for whether each variable is balanced across arms and the last column conducts a pairwise t-test of the mean difference between columns 2 and 3. "SC/ST" is abbreviation for Scheduled Caste/ Scheduled Tribe. Standard errors are clustered at the level of treatment assignment (village) and reported below mean values for each variable. The F-test of joint significance omits the highest household income category to test for variance across all variables. The number of observations are included in the last row. $*$ p$<$ 0.1, $**$ p$<$ .05, $***$ p$<$ .01

Table 2: Instrumental Variables: First stage

Baseline controls	Yes	Yes	Yes	Yes	Yes	Yes
Block fixed effects	Yes	Yes	Yes	Yes	Yes	Yes

Notes: The table reports the ITT and LATE estimates of the loan product on household ownership of assets (listed as column titles). The dependent variables are binary and constructed from survey questions on whether household owns the following: Column 1 includes non-mechanized equipment for farming such as hand tools, animal-drawn plows and non-mechanized irrigation tools. Column 2 includes mechanized farm equipment such as electric pump-set, diesel pump-set, tractor, seeder, power-tiller, thresher, combine harvester etc. Column 3 includes non-farm business equipment such as sewing machines and solar panels. Column 4 includes large consumer durables such as refrigerator, TV, sofa, dining table, chair, mattress, cot or bed, computer, washing machine. Column 5 includes small consumer durables (radio or transistor, pressure cooker, an inverter, electric fan, watch or clock, landline phone). The model includes outcome variable and covariates from the baseline survey as regressors and block fixed effects.Sharpened q-values are reported in curly braces. A family consists of the three outcomes within a panel, and LATE and ITT estimates are treated as separate families. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

Table 4: ITT: Food Consumption Score (FCS)

	(1)	
Panel A: Household food consumption score		
ITT estimate	5.611*	
	(2.845)	
Observations	701	
Mean dependent variable (Baseline)	33.799	
Covariates included	Yes	
Block fixed effects	Yes	
Panel B: Individual food consumption score (24 hrs recall)		
	Women	Men
	(1)	(2)
LATE estimate	1.966*	2.829*
	(1.183)	(1.552)
Observations	395	342
Control group mean	10.661	10.661
Covariates included	Yes	Yes
Block fixed effects	Yes	Yes

Notes: The table reports the effect of loan treatment on food consumption score in panel A (ITT estimates), and the effect of a household receiving the loan product on individual food consumption score in last 24 hours in panel B (LATE estimates). Panel A uses an ANCOVA model where outcome variables and covariates measured at baseline are used as regressors in the estimation. Panel B uses treatment assignment as an exogenous instrument for the household's receipt of loan product. All models control for the household's demographic and economic characteristics from the baseline survey and includes block fixed effects. Standard errors are clustered at the level of treatment assignment (village) and reported in parentheses. $*$ p$<$ 0.1, $**$ p$<$ .05, $***$ p$<$ .01

Baseline controls	Yes	Yes	Yes	Yes	Yes	Yes
Block fixed effects	Yes	Yes	Yes	Yes	Yes	Yes

Notes: The table reports LATE and ITT estimates of the loan product on household members' bank account ownership and debit card use. LATE estimates are from a 2SLS model using village assignment to treatment as an instrument for a household's receipt of the loan product. ITT estimates are from ordinary least squares regressions of the outcome on village assignment to treatment, estimated on the same sample as the corresponding LATE. The dependent variables (binary) are listed as column titles. Panel A restricts the sample to women in the endline survey and Panel B to men. All regressions control for the household's demographic and economic characteristics from the baseline survey and include block fixed effects. The first-stage F is the F statistic for regressing village assignment on household's receipt of the loan product, conditional on the controls and fixed effects. Standard errors in all models are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q-values are reported in curly braces. A family consists of the three outcomes within a panel, and LATE and ITT estimates are treated as separate families. The test of equality of coefficients between women and men assumes independence between the two samples. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

Notes: The table reports LATE and ITT estimates of the loan product on household members' phone ownership and use of mobile app banking. LATE estimates are from a 2SLS model using village assignment to treatment as an instrument for a household's receipt of the loan product. ITT estimates are from ordinary least squares regressions of the outcome on village assignment to treatment, estimated on the same sample as the corresponding LATE. The dependent variables (binary) are listed as column titles. Panel A restricts the sample to women in the endline survey and Panel B to men. All regressions control for the household's demographic and economic characteristics from the baseline survey and include block fixed effects. Sample sizes differ as non-response to the mobile ownership questions are marked missing. The first-stage F is the F statistic for regressing village assignment on household's receipt of the loan product, conditional on the controls and fixed effects. Standard errors in all models are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q-values are reported in curly braces. A family consists of the three outcomes within a panel, and LATE and ITT estimates are treated as separate families. The test of equality of coefficients between women and men assumes independence between the two samples. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

Notes: The table reports LATE and ITT estimates of the loan product on household members' time use in the day before the survey, measured in hours. LATE estimates are from a 2SLS model using village assignment to treatment as an instrument for a household's receipt of the loan product. ITT estimates are from ordinary least squares regressions of the outcome on village assignment to treatment, estimated on the same sample as the corresponding LATE. The dependent variables are listed as column titles (see Table B.1 for description). Panel A restricts the sample to women in the endline survey and Panel B to men. All regressions control for the household's demographic and economic characteristics from the baseline survey and include block and interview month fixed effects. The first-stage F is the F statistic for regressing village assignment on household's receipt of the loan product, conditional on the controls and fixed effects. Standard errors in all models are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q-values are reported in curly braces. A family consists of the six outcomes within a panel, and LATE and ITT estimates are treated as separate families. The test of equality of coefficients between women and men assumes independence between the two samples. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

11 Online Appendix A: Theoretical Model

A.1 Set-up

Consider a two-member household with members $i \in \{A, B\}$. Each member derives utility from private consumption goods $q^i \geq 0$, leisure $l_i \geq 0$, and financial autonomy $\alpha_i \geq 0$, defined as the member's independent access to and use of financial services. Following Bobonis (2009), the household jointly consumes a public good $K \geq 0$ and a composite good $C = C^A + C^B + C^H \geq 0$, where C^A and C^B denote the shares consumed privately by each member and C^H denotes the jointly consumed share. Consumer durables and productive assets, such as farm and business equipment, are examples of composite goods that generate utility for both members.

Each member is endowed with time T and faces a wage rate w^i. Individual non-labor income is y^i, and the household receives joint non-labor income y^O. Total household resources are:

$$Y = \sum_{i \in \{A,B\}} \left(y^i + w^i T\right) + y^O. \tag{4}$$

Member i's preferences are represented by a utility function $U^i(q^i, l_i, \alpha_i, C, K)$, which is strictly increasing, twice continuously differentiable, and strictly quasi-concave in all arguments. We impose two assumptions that are relevant to the program context.

Assumption 3. *The household treats the loan L as an increase in joint non-labor income in the short term: $y^O \mapsto y^O + L$.*

Assumption 4. *Leisure and financial autonomy are normal goods for each member.*

Assumption 1 reflects the organization of farm production at the household level and the program design where two household members co-signed the loan, which makes a loan for farming likely to be treated as a joint resource. Assumption 2 implies that a member whose residual income rises consumes more leisure and financial autonomy.

A.2 Household Optimization

Under Pareto optimality, a household's allocation is characterized as the solution to a weighted utility maximization. Let $\mu \in (0, 1)$ denote member A's bargaining or Pareto weight, while $1 - \mu$ is member B's weight. The household solves:

$$\max_{\{q^i, l_i, \alpha_i\}, C, K} \; \mu\, U^A(q^A, l_A, \alpha_A, C, K) + (1 - \mu)\, U^B(q^B, l_B, \alpha_B, C, K) \tag{5}$$

subject to the household budget constraint:

$$\sum_i \left(p_q q^i + p_\alpha \alpha_i + w^i l_i\right) + p_C C + p_K K \leq Y \tag{6}$$

and the non-negativity constraints $q^i, l_i, \alpha_i, C, K \geq 0$ for all i.

Following Browning and Chiappori (1998) and Bobonis (2009), we allow μ to be a function of distribution factors, variables that affect bargaining power without entering preferences or the budget constraint:

$$\mu = \mu\big(y^A, y^B, w^A T, w^B T, y^O, z\big)\,, \tag{7}$$

where z is a non-monetary distribution factor that affects bargaining power without entering preferences or the budget constraint. Under this formulation, the loan affects intrahousehold allocations through two distinct channels: it relaxes the household budget constraint, an income effect common to both members, and it may shift the Pareto weight, a distributional effect that reallocates resources between members.

A.3 Two-Stage Budgeting

Following Blundell et al. (2005) and Bobonis (2009), the optimization problem can be represented as a two-stage process that distinguishes the loan's effects on household-level and individual-level consumption.

Stage 1. Given total household resources Y and the Pareto weight μ, the household chooses expenditure on the public and composite goods. Let $C^*(Y, \mu)$ and $K^*(Y, \mu)$ denote the Stage 1 optima. By Stylized Fact 1, $\partial C^*/\partial Y > 0$: the loan raises composite good consumption for the household as a whole. If members value C and K, this channel generates a welfare gain for all members irrespective of how the loan affects bargaining.

Productive assets enter the model as composite goods, in the same way as consumer durables because they can be consumed both jointly and independently. Unlike consumer durables, however, farm and business equipment can also affect household output and the household's demand for members' labor. These production effects operate alongside the consumption response described in the model.

The household also determines each member's contribution $s^i \geq 0$ to Stage 1 expenditure through an intrahousehold sharing rule:

$$s^i = \phi^i(\mu, Y, z), \qquad \sum_i s^i = p_C C^* + p_K K^* - y^O. \tag{8}$$

Stage 2. Conditional on C^* and K^*, each member i chooses private consumption to maximize utility subject to an individual residual income constraint. Member i's residual income is:

$$\rho^i = y^i + w^i T - s^i. \tag{9}$$

Member i solves:

$$\max_{q^i, l_i, \alpha_i} \; U^i(q^i, l_i, \alpha_i, C^*, K^*) \quad \text{s.t.} \quad p_q q^i + p_\alpha \alpha_i + w^i l_i \leq \rho^i, \tag{10}$$

with C^* and K^* taken as given. Financial autonomy and leisure are therefore chosen from residual income, $\alpha_i^* = \alpha_i(\rho^i, \cdot)$ and $l_i^* = l_i(\rho^i, \cdot)$, with $\partial \alpha_i^* / \partial \rho^i > 0$ and $\partial l_i^* / \partial \rho^i > 0$ by Assumption 2. The solution to (10) yields member i's indirect utility $V^i(\rho^i, C^*, K^*)$, which is strictly increasing in residual income, composite and public goods. The total effect of the loan on member i's welfare decomposes as:

$$\frac{dV^i}{dL} = \underbrace{\frac{\partial V^i}{\partial C^*} \cdot \frac{\partial C^*}{\partial L}}_{>0} + \underbrace{\frac{\partial V^i}{\partial K^*} \cdot \frac{\partial K^*}{\partial L}}_{\geq 0} + \underbrace{\frac{\partial V^i}{\partial \rho^i} \cdot \frac{d\rho^i}{dL}}_{\gtrless 0}. \tag{11}$$

The first term is strictly positive, since utility is strictly increasing in composite goods and the loan raises their consumption (Stylized Fact 1). The second term is weakly positive if the loan does not reduce public good consumption. The sign of the third term depends on how the loan affects member i's residual income.

A.4 The Effect of the Loan on Residual Income

The loan affects individual residual income in the short term in two ways. One is a bargaining channel, where if the loan shifts the Pareto weight in member i's favor, their required contribution s^i falls and ρ^i rises. The other is the resource expansion channel. Holding the Pareto weight fixed, the household can finance joint expenditure from the loan rather than from members' own earnings, reducing their required contributions. Member i's residual income rises whenever their required contribution falls. By the adding-up condition in (8), if total contributions fall, both members' contributions can fall; if total contributions rise, a fall in one member's contribution requires a rise in the other's. We characterize the welfare implications of the loan on individuals by considering three cases.
Case (i): $d\rho^i/dL > 0$. The loan increases member i's residual income, either because it strengthens their bargaining position or because the resource expansion channel reduces their required contribution to household expenditure. All three terms in (11) are weakly positive, and the loan is welfare-improving for member i. By Assumption 2, the expanded residual income allows member i to increase leisure and financial autonomy above their pre-loan optima.
Case (ii): $d\rho^i/dL = 0$. The loan leaves member i's residual income unchanged, as the bargaining and resource expansion effects on s^i offset one another or neither operates. The welfare effect in (11) is positive as the first two terms are positive and the third term equals zero. Member i benefits from the household-level consumption gains but

experiences no change in private consumption, leisure, or financial autonomy. This case is consistent with a household that allocates the loan entirely to joint expenditure without altering the internal distribution of private resources.

Case (iii): $d\rho^i/dL < 0$. The loan reduces member i's residual income, as the shift in bargaining power increases their required contribution s^i. The net welfare effect is now ambiguous. When the residual income loss is small relative to the gains in jointly consumed goods, $dV^i/dL > 0$ and the loan remains welfare-improving. When the loss is large enough to dominate, $dV^i/dL < 0$. The scenario in case (iii), where a positive household income shock leaves an individual member worse off, cannot be detected in a unitary model, further motivating the collective framework.

A.5 Testable Hypotheses

We analyze first-stage changes in household consumption of composite goods through the ownership of farm and business equipment and consumer durables, and report the household's food consumption score as an additional household-level outcome. In the second stage, we do not directly observe individual residual income, but interpret its effects through members' financial autonomy, measured as the independent use of debit cards and mobile apps for banking, and through time allocated to personal activities, farm work, and non-farm work. In our empirical analysis, we do not impose the assumption that time endowment is fixed or the identity that labor supply is $T - l_i$ because we did not collect a 24 hours recall but asked members the time they allocated to specific production and consumption activities listed in Table B.1. We test for the resource expansion channel through self-reported account activity, such as deposits, and for the bargaining channel through members' self-reported involvement in decisions on production and consumption.

The model predicts that a rise in residual income increases leisure.Productive assets, however, can also change the household's demand for members' labor. We observe only the aggregate labor response, which is net of changes in labor demand and the increase in leisure, and cannot separate the two.

12 Appendix B: Outcome Variables

Household outcomes

Our primary household-level outcomes are binary variables of assets owned by the household and the World Food Programme's Food Consumption Score that measures dietary diversity. We analyze secondary outcomes of agricultural production to interpret impacts on household members' time use. These are area cultivated (in hectares), real income from farming, and household expenditure on inputs such as irrigation, seeds, fertilizers,

labor, and land and machinery rental. All household-level outcomes were collected in both baseline and endline surveys.

Individual outcomes

We group individual-level outcomes into three categories: financial autonomy, time use, and involvement in decision-making. Financial autonomy and time use were measured only at endline. Questions on decision-making were asked of the panel respondent at both baseline and endline, and of the additional respondent at endline only.

Financial autonomy: We expect if the loan expanded resources available to household members, it would be observable in their bank account activity and expression of financial autonomy through the use of ATM cards and mobile banking. We asked respondents whether they owned an individual bank account, used the debit card linked with this account on their own or shared it with their spouse and/or other family members. We also asked them to report how frequently they deposited/ withdrew funds or received salary or transfer payments in to their bank account. Finally, we asked if they had knowledge of and ever used mobile apps for banking. These binary indicators take the value 1 when individual responded yes, and 0 otherwise. Schaner (2016) found that debit cards are perceived to lower transaction costs of resource appropriation from individual bank accounts, and women reduced their account usage when provided a debit card. We investigate whether members are sharing their debit card or using it autonomously to infer their financial autonomy and control over resources. We measure their knowledge and use of mobile app-based banking because it enhances privacy and lowers the transaction costs of physically traveling to a bank branch or ATM for deposit or withdrawal. These apps are growing in popularity through low-cost internet plans and mobile phones, and steady promotion of digital transactions by the Indian government and the Reserve Bank of India (CGAP, 2019).

Time use: Hidrobo et al. (2016); Fink et al. (2020); El-Enbaby et al. (2025) show that loans and transfers to farming households impact the time use of members.The loan may affect household members' labor allocation to production activities either through expansion and intensification of input use or it may reduce demand for their labor through tools that allow members to work more productively. We asked household members to report the time they spent in the past day and during a busy day in the last agricultural season ("peak time") on various production activities such as farming, horticulture, livestock management, poultry, fishpond, and non-farm economic activities such as business, self-employment and wage employment. We also investigated non-production activities such as household purchases, domestic work and personal activities. Questions on time use were added on to a module on participation from the baseline survey (that was in

turn adapted from the PRO-WEAI module and described below).[22] Time allocations under these activities do not add upto 24 because respondents were asked the time they spent on activities in Table B.1 conditional on them reporting they participated in that activity.

Decision-making: We use self-reported survey measures of decision making consistent with the literature measuring women's intrahousehold bargaining power (Allendorf, 2007; Connelly et al., 2010; Swaminathan et al., 2012; Field et al., 2021; Annan et al., 2021; Kosec et al., 2022; Heckert et al., 2023; Doss et al., 2022; Quisumbing et al., 2023a,b). We asked questions about members' involvement in the last 12 months in decisions around production and non-production activities such as farming, livestock and poultry, non-agricultural work and consumption (see Table B.1 for description). These questions were adopted from the project-level Women's Empowerment in Agriculture Index (pro-WEAI). We measure "involvement" as a combination of solo and joint decision making with other household members as we did not collect individual's preferences on which type of decisions they wanted to make.[23] We also test separately women's decision making jointly with their spouse.

We included a question on each member's share of individual income from different production activities but do not analyze it as the question was administered incorrectly by the enumerators during the survey. We do not test women's uptake of credit in response to the program as the loan was co-signed by two household members and not specifically targeted to any one household member.

[22] In the endline, we included the same activities from the baseline survey and added consumption decisions such as large and daily household purchase decisions, private consumption and personal activities (which includes leisure). Following the structure of the baseline survey, this module required a skip to the next activity if respondents said they did not participate. So respondents were not asked their time allocation if they said did not participate in that activity.

[23] Kochar et al. (2022) highlights that some decisions, such as those concerning food preparation, align with gender stereotypes about women's role in the household, and that delegating these tasks to women may reflect their lower agency.

Table B.1: Variable description of activities

Variable	Description
Farming	- Farming and processing of the harvest: grains that are grown primarily for food consumption (rice, maize, wheat, millet) - Horticultural (gardens) or high value crop farming and processing of the harvest
Livestock & Poultry	- Raising cattle, buffaloes, sheep, goats, pigs and processing of their milk and/or meat; raising chickens, ducks, turkeys and processing their eggs and/or meat
Non-agriculture	- Small business, self-employment, buy-and-sell - Wage and salary employment
Household purchases	- Large, occasional household purchases (bicycles, land, transport vehicles) - Routine household purchases (food for daily consumption or other household needs)
Domestic work	Cooking, cleaning, fetching firewood or water, and caring for children or others
Personal activity	Eating, leisure such as visiting neighbors, watching TV, listening to the radio, seeing movies, or doing sports

Notes: Variable generation for analyzing time use and decision making from individual activities asked in the survey.

13 Online Appendix C. Figures

C.1 Sources of formal loan by intervention arm 50
C.2 Distribution of sample by credit score 50
C.3 Distribution of propensity to borrow by intervention arm 51

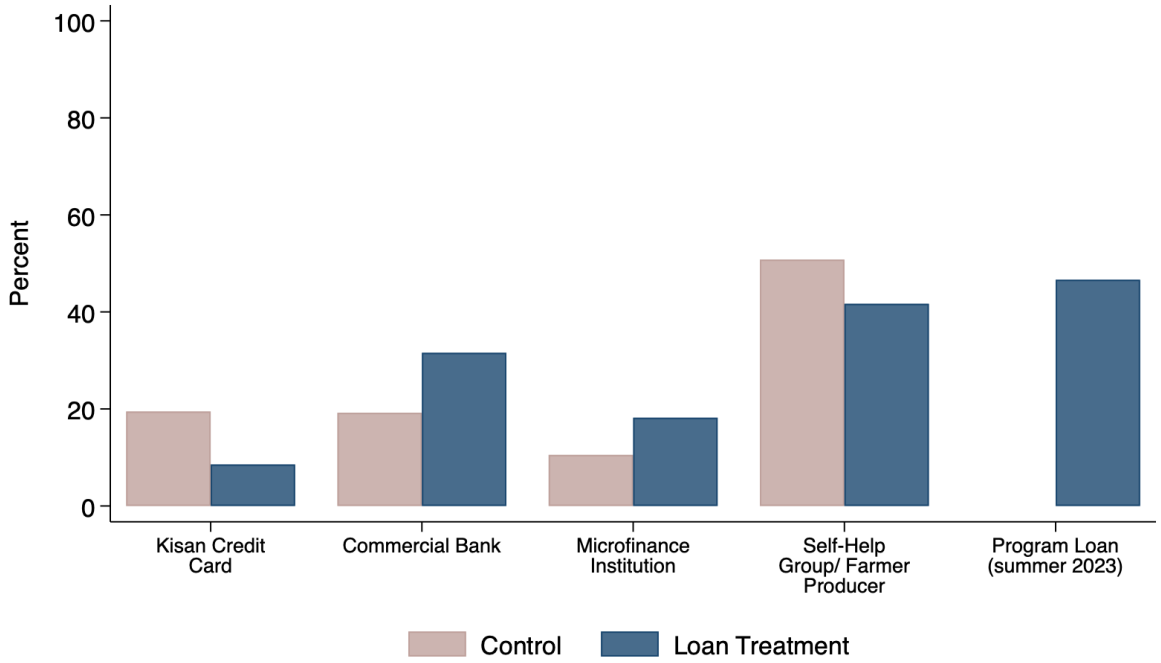

Figure C.1: Sources of formal loan by intervention arm

Notes: The figure plots the distribution of uptake of formal sources of credit for the summer planting season in 2023 reported by households in the endline survey.

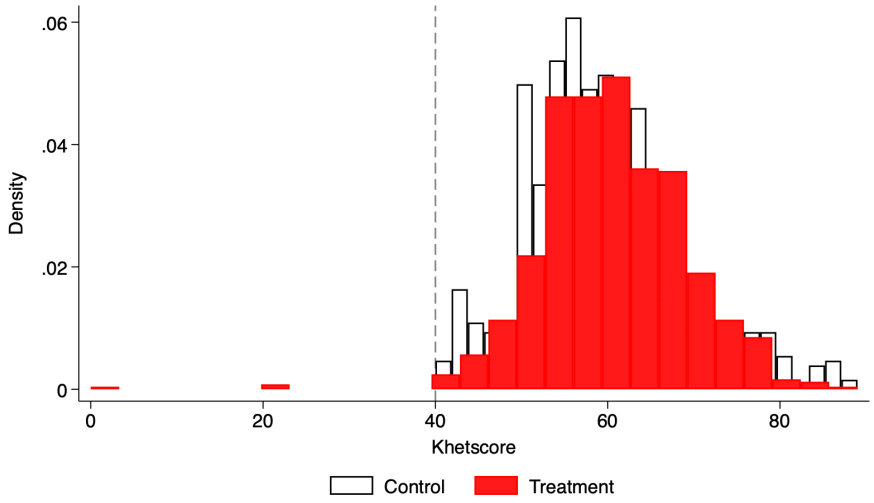

Figure C.2: Distribution of sample by credit score

Notes: The figure plots the distribution of credit score of households in the control (black outline) and treatment arm (solid red). The score is a weighted index computed by DER and the loan eligibility threshold was 40.

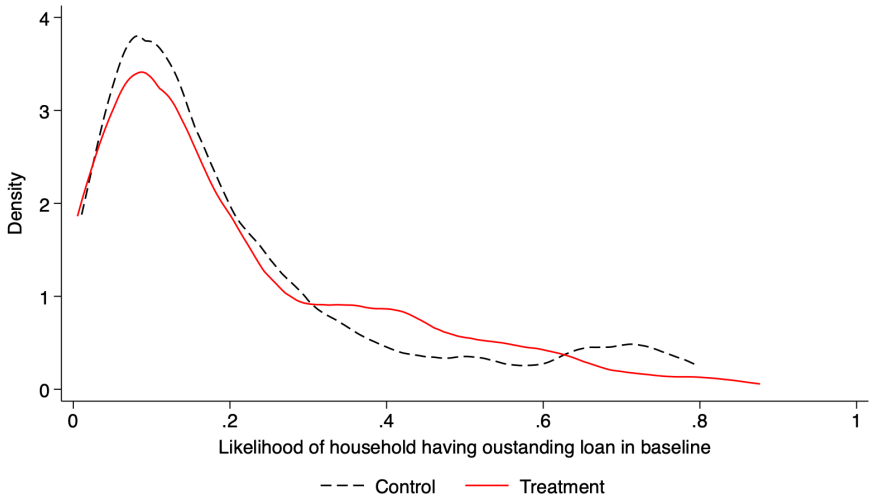

Figure C.3: Distribution of propensity to borrow by intervention arm

Notes: The figure plots the propensity score distributions of households receiving any loan at baseline in the control (dashed line) and treatment arm (solid line). The score is estimated using a logit model where the outcome is a binary variable of whether the household had an outstanding loan and the explanatory variables are household characteristics from the baseline survey.

Table D.1: Cost of the loan program and net returns

Fixed costs (per season)		
Project management	8733.33	
Staff travel	1071.33	
Field office cost	4000.00	
App/portal maintenance	5158.67	
Communication material	178.67	
Total fixed cost per season	19142.00	
Total fixed cost per farmer	30.58	
	Maharashtra	Odisha
Variable costs (per farmer)		
Khetscore report	5.5	5.5
DER field staff	10.56	10.56
Staff transport, allowance	2.079	2.156
Printing, stationary	0.352	0.363
Total Variable cost per farmer	18.491	18.579
Interest 14% of loan	72.38	63.14
Number of beneficiaries	160	193
Defaulters	0	3
Total costs= (fixed + variable)	7851.36	9487.69
Total revenue	11580.80	11996.60
Net return	3729.44	2508.91
Net return per farmer	23.31	13.00

Notes: The cost of the program (in USD) is compiled using data shared by DER. Total cost per farmer is estimated using total farmers who received the loan product across the entire intervention, which included two treatment arms. This paper only analyzes the loan treatment arm while Xu et al. (2026) documents the additional loan and insurance treatment.

Table D.2: Attrition by treatment assignment and baseline characteristics

	Sample that attrited	
	(1)	(2)
Treatment: Loan	-0.038	-0.033
	(0.036)	(0.037)
Respondents' age		0.001
		(0.002)
Respondent is female		0.061**
		(0.025)
Can read and write		0.027
		(0.029)
Completed at least primary school		-0.008
		(0.027)
Completed at least secondary school		-0.013
		(0.025)
Respondent belongs to SC/ST category		-0.023
		(0.022)
Respondent is married		0.021
		(0.031)
Annual Household Income(<90,000)		0.024
		(0.029)
Annual Household Income (> 120,000)		0.024
		(0.024)
Owns land		-0.004
		(0.024)
Respondent has bank account		-0.044
		(0.044)
Borrowed money last 12 months		0.018
		(0.024)
Have outstanding loan		-0.059*
		(0.033)
Constant	0.152***	0.134
	(0.023)	(0.083)
Observations	1682	1682
Non-attrited (N)	1431	1431
Block dummies	Yes	Yes
Mean dep. variable	0.149	

Notes: The table reports reduced form estimation of whether attrition of the sample was significantly correlated with treatment assignment (column 1) or ex-ante characteristics of the household measured from the baseline survey (column 2). The binary dependent variable distinguishes the sample that was interviewed at baseline and not in the endline survey. Both models include block fixed effects. Standard errors are clustered at the level of treatment assignment (village) and reported in parentheses. The average sample that attrited in the control group is reported in the last row of column 1. $*$ p< 0.1, $**$ p< .05, $***$ p< .01

Table D.3: Administrative data on loan take-up

	Summer 2023	
	Control	Loan Treatment
	(1)	(2)
Applied for loan (% total)	0	58.5
Received loan (% total)	0	47
Returned successfully (% total)	0	46.79
Loan amount (INR)	0	41, 505
DER generated Credit score	58.9	60.5
Observations	681	748

Notes: The table reports the disbursal of the program's loan product to households in the control and treatment arm. Column 1 verifies the validity of the experiment design as no control group households were given the loan. This data is extracted from the loan records of the implementing partner DER.

Table D.4: Balance test of outcome variables at baseline

		(1)		(2)		(3)	F-test for balance	(2)-(3)

Baseline Controls	Yes	Yes	Yes
Block fixed effects	Yes	Yes	Yes

Notes: The table reports LATE estimates of the loan product on household members' withdrawal, deposit and money receipt in their bank account. We asked household members their frequency of account deposits and withdrawals and found 44% of them deposited funds in their account 2-3 times a month and about 51% withdrew funds with the same frequency, while weekly deposit and withdrawal were less than 3%. Therefore, we analyze differences in account transactions with the frequency of 2-3 times a month. LATE estimates are from a 2SLS model using village assignment to treatment as an instrument for a household's receipt of the loan product. The dependent variables (binary) are listed as column titles. Panel A restricts the sample to women in the endline survey and Panel B to men. All regressions control for the household's demographic and economic characteristics from the baseline survey and include block fixed effects. The first-stage F is the F statistic for regressing village assignment on household's receipt of the loan product, conditional on the controls and fixed effects. Standard errors in all models are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q-values are reported in curly braces and a family consists of the three outcomes within a panel. The test of equality of coefficients between women and men assumes independence between the two samples. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

Table D.15: LATE: Heterogeneous effects in reports of time allocations (peak time) by individual account ownership

Notes: The table reports LATE and ITT estimates of the loan product on women's involvement in decision making. LATE estimates are from a 2SLS model using village assignment to treatment as an instrument for a household's receipt of the loan product. ITT estimates are from ordinary least squares regressions of the outcome on village assignment to treatment, estimated on the same sample as the corresponding LATE. The dependent variables are listed as column titles. See Table B.1 for description of column titles. Panel A restricts the sample to women in Odisha and Panel B to women in Maharashtra. All regressions control for the household's demographic and economic characteristics from the baseline survey and include block and interview month fixed effects. The first-stage F is the F statistic for regressing village assignment on household's receipt of the loan product, conditional on the controls and fixed effects. Standard errors in all models are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q-values are reported in curly braces. For both corrections, a family consists of the eight outcomes within a panel, and LATE and ITT estimates are treated as separate families. Stars refer to conventional p-values: $*p < 0.1, **p < .05, ***p < .01$

Table D.23: LATE: Loan intervention and joint decision making with spouse

Baseline Controls	Yes	Yes	Yes	Yes
Block fixed effects	Yes	Yes	Yes	Yes

Notes: The table reports LATE estimates of loan treatment on decisions made jointly with their spouse. The analysis uses treatment assignment as an exogenous instrument for a household's receipt of the loan product. The outcome variables are binary and take the value 0 if the woman is not involved in the decision or makes the decision on her own. Column 1 includes farming and processing of the harvest for food consumption and high value crop farming. Column 2 includes management of large livestock (e.g. cattle and buffaloes), small livestock (sheep, goats, pigs) and poultry. Column 3 includes non-farm economic activities such as small business, self-employment and wage and salary employment. Column 4 includes decisions on purchase of large items such as bicycles, land and transport vehicles as well as routine items such as food. The sample is restricted to women in the endline survey in Panel A and men in Panel B. Therefore, only one observation per household is analyzed. The estimation controls for the household's demographic and economic characteristics from the baseline survey and includes block fixed effects. Standard errors are clustered at the level of treatment assignment (village) and reported in parentheses. $*$ p$<$ 0.1, $**$ p$<$ .05, $***$ p$<$ .01

Notes: The table reports heterogeneous LATE estimates by baseline asset quintile, estimated by 2SLS. Loan take-up and its interaction with the baseline asset quintile are treated as endogenous and instrumented with village assignment to treatment and its interaction with the baseline asset quintile. Dependent variables are the number of hours spent in an activity and listed as column titles. The estimation controls for the household's demographic and economic characteristics from the baseline survey and includes block fixed effects. Standard errors are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q values are computed separately for all outcomes within each gender panel, therefore, a family consists of the outcomes within a gender panel. Stars refer to conventional p-values: $*$ p$<$ 0.1, $**$ p$<$ .05, $***$ p$<$ .01

Notes: The table reports averages of respondent and household characteristics from the baseline survey by category of application status. Column 1 reports pooled estimates for the full sample. Column 2 reports the averages for households in the loan treatment arm that applied for the loan and received it. Column 3 describes households in the treatment arm that were unsuccessful in getting the loan and column 4 includes households in the treatment arm that did not apply for the loan. Column 5 describes households in the control arm. The fifth column reports the f test for whether each variable is balanced across arms and the last column provides coefficients of a t-test comparing the treatment and control averages. "SC/ST" is abbreviation for Scheduled Caste/ Scheduled Tribe. Standard errors are clustered at the level of treatment assignment (village) and reported below mean values for each variable. The number of observations are included in the last row. $*$ p< 0.1, $**$ p< .05, $***$ p< .01

Table D.40: LATE: Independent bank account and debit card use re-weighted by propensity to borrow

	Own bank account (1)	Deposited money (2)	Withdrew money (3)	Received money (4)	Use debit card alone (5)	Share debit card (6)

Baseline Controls	Yes	Yes	Yes	Yes	Yes	Yes
Block fixed effects	Yes	Yes	Yes	Yes	Yes	Yes

Notes: The table reports LATE estimates of treatment on bank account ownership and use of debit card. Each household is weighted by the inverse of their ex-ante propensity to borrow. The analysis uses treatment assignment as an exogenous instrument for a household's receipt of the loan product. The dependent variables (binary) are listed as column titles. Panel A restricts the sample to women in the endline survey and Panel B to men. The estimation controls for the household's demographic and economic characteristics from the baseline survey and includes block fixed effects. Standard errors are clustered at the level of treatment assignment (village) and reported in parentheses. Sharpened q values are computed separately for all outcomes within each gender panel, therefore, a family consists of the outcomes within a gender panel. Stars refer to conventional p-values: $*$ p$<$ 0.1, $**$ p$<$ .05, $***$ p$<$ .01

Table D.41: LATE: Mobile phone and digital financial services re-weighted by propensity to borrow
